Abstract

Background: High-throughput whole genome sequencing facilitates investigation of minority sub-populations from virus positive samples. Minority variants are useful in understanding within and between host diversity, population dynamics and can potentially help to elucidate person-person transmission chains. Several minority variant callers have been developed to describe the minority variants sub-populations from whole genome sequence data. However, they differ on bioinformatics and statistical approaches used to discriminate sequencing errors from low-frequency variants.

Methods: We evaluated the diagnostic performance and concordance between published minority variant callers used in identifying minority variants from whole-genome sequence data. The ART-Illumina read simulation tool was used to generate three artificial short-read datasets of varying coverage and error profiles from an RSV reference genome. The datasets were spiked with nucleotide variants at predetermined positions and frequencies. Variants were called using FreeBayes, LoFreq, Vardict, and VarScan2. The variant callers’ agreement in identifying known variants was quantified using two measures; concordance accuracy and the inter-caller concordance.

Results: The variant callers reported differences in identifying minority variants from the datasets. Concordance accuracy and inter-caller concordance were positively correlated with sample coverage. FreeBayes identified majority of the variants although it was characterised by variable sensitivity and precision in addition to a high false positive rate relative to the other minority variant callers and which varied with sample coverage. LoFreq was the most conservative caller.

Conclusions: We conducted a performance and concordance evaluation
of four minority variant calling tools used to identify and quantify low frequency variants. Inconsistency in the quality of sequenced samples impact on sensitivity and accuracy of minority variant callers. Our study suggests that combining at least three tools when identifying minority variants is useful in filtering errors when calling low frequency variants.

Introduction
RNA viruses have been described as a population of closely related sequences that arise from rapid genomic evolution coupled with a high replication and mutation rates (Domingo et al., 2012; Eigen et al., 1988; Holland et al., 1992). Genetic changes in RNA viruses result from genetic drift, erroneous replication processes and mutagenic agents and upon which natural selection acts (Moya et al., 2004). Rapid replication and mutations generate an ensemble of mutant genomes comprised of dominant and low frequency variants. This diversity has been shown to affect virus fitness landscape, transmission, colonization, and replication (Henn et al., 2012; Stack et al., 2013; Vignuzzi et al., 2006).

A number of recent studies have demonstrated the potential application of virus diversity to inform person-to-person transmission during virus outbreaks (Henn et al., 2012; Poon et al., 2016; Stack et al., 2013). A number of methods that incorporate both genomic and epidemiologic data to infer pathogen transmission have recently been developed (Worby et al., 2017). These approaches rely partly on the accurate detection and quantification of minority variant populations from genomic samples.

Several tools have been developed to identify and quantify minority variants from short-read data (Koboldt et al., 2009; Koboldt et al., 2012; Lai et al., 2016; Macalalad et al., 2012; Wilm et al., 2012; Yang et al., 2013). Nonetheless, these tools do not fully account for errors or discrepancies that arise from sample collection, pre-processing, sequencing in addition to errors introduced during bioinformatic analysis. Rigorous quality control in sample processing and analysis is often suggested to distinguish true biological variants from artefactual variants (Zhang & Flaherty, 2017). In some cases, sequencing errors can be reduced by developing high-fidelity protocols and laboratory quality control measures (Kinde et al., 2011; McCrone & Lauring, 2016; Watson et al., 2013). Additionally, the uncertainty resulting from random sequencing errors can be countered by sequencing larger populations at higher coverage (Zukurov et al., 2016).

Several studies have extensively explored variants from somatic or tumour samples (Hofmann et al., 2017; Koboldt et al., 2012; Kroigard et al., 2016; Lai et al., 2016; Pabinger et al., 2014) and their application in clinical genomics, but only a limited number of studies have explored the nature of variants from patient-derived samples that target viral populations (Henn et al., 2012; Macalalad et al., 2012; Wilm et al., 2012; Yang et al., 2013; Zukurov et al., 2016) and especially when calling variants from respiratory viruses such as the respiratory syncytial virus (RSV).

In this study, we evaluated five published minority variant detection tools using both artificial and real RSV short-read data from a household community study. We explored their ability to detect and quantify minority variants and assessed their overall agreement which we defined using two metrics, concordance accuracy, which measures the combined accuracy of the variant callers and inter-caller concordance, which is the size of the largest set of variant callers that agree at each position. We show that concordance metrics are dependent on sample coverage and are influenced by the quality of input data.

Methods
Overall, we considered eleven published, open-source tools with presumed ability to call minority variants from virus deep sequence data. Some of the callers were excluded from the analysis for various reasons including deprecation, ease of setup, and accepted input, among other reasons (Table 1). The following four tools were evaluated, FreeBayes version 1.1.0-3-g961e5f3, LoFreq version 2.1.2, VarDict version 30.3.17 and VarScan version 2.4.2. A schematic diagram showing the overall approach is shown in Figure 1.

Artificial datasets
Three artificial datasets were generated based on an RSV reference sequence (GenBank accession number KX510245.1) using ART-Illumina version 2.5.8 (Huang et al., 2012). Each dataset comprised of eight samples with varying depth of coverage (20, 50, 100, 500, 1000, 2000, 5000, 10000) generated using methods described in Supplementary File 1, section S1.1.

Table 1. A table of the exclusion criteria used to discard commonly used variant callers from the analysis.
The first dataset did not contain an error profile while the second and third datasets comprised of artificial reads with an error profile that was derived from sequenced RSV whole genome samples and subjectively comprised of a “good” and a “bad” sample judged from FastQC metrics (Supplementary File 2 and Supplementary File 3) from the respective sequenced short read data. For each sample, ART-Illumina artificial SAM files were converted to BAM format, sorted and indexed using SAMtools version 1.3.1.

166 randomly and uniformly generated nucleotide mutations at varying frequencies were inserted into each of the artificial datasets using BamSurgeon (Ewing et al., 2015), such that a base change was made amongst the reads at each alignment position as described in Supplementary File 1, section S1.2.

Variant calling

The BAM files from each of the three datasets were used as input to each of the four variant callers (FreeBayes, LoFreq, VarDict and VarScan2). All output files were provided in the variant call format (VCF) or as a tabular file for the case of VarDict. Where multithreading was possible, the tool was run in multithreaded mode. For example, LoFreq calls were run in parallel using 10 threads. The output from the VCF and tabular file was parsed and written as a comma separated (CSV) files.

Performance measures

To evaluate the performance of the variant calling algorithms, we compared the sequence generated by each variant caller \( v_c \), denoted \( S_c = \{S_c^{(i)} \in \{A,C,T,G\} \}_{i=1,...,N} \), to the gold standard “spiked” sequence, denoted \( S^{true} \), at each of \( N=15205 \) nucleotide positions. The accuracy of each variant caller is the normalized Hamming distance from the gold standard sequence, 

\[
\bar{d} = \frac{1}{N} \sum_{i=1}^{N} d(S_c^{(i)}, S^{true^{(i)}}),
\]

where \( d(x,y) \) is the standard discrete metric giving 1 when \( x=y \), and 0 otherwise. By distinguishing between the sets of positions where variants did and did not occur (shown in Table 2), in the gold standard sequence we calculated sensitivity, specificity, precision and accuracy (Table 3).

Concordance analysis

We defined two concordance metrics to present the level of agreement between different callers in detecting the same variant positions in the sequence. The first concordance metric is concordance accuracy, which measures the combined

</table>
accuracy of the variant callers. At the true variant position $i$ we then $C_{.mc}(i) = \sum_{vc \in \text{set}} d(S^{vc}, S^{i})$, which can be either 0, 1, 2, 3, 4 for each true variant position. The second concordance metric is inter-caller concordance, which is the size of the largest set of variant callers that agree at each position $i$, without reference to any gold standard sequence. We used both bar plots and heat maps to visualize the effect of coverage on $C_{mc}$. Visualization of inter-caller concordance for variant sets was achieved using a bar plot and expounded by UpSet plots (Lex et al., 2014) in R version 3.4.2.

**Results**

We used three artificial datasets of varying coverage and error profile to assess the concordance accuracy and inter-caller concordance for four minority variant callers. The first dataset comprised of artificial reads based on an RSV genome, the second dataset comprised of the similar simulated set of reads whilst incorporating an error profile from the set of reads used to assemble the reference genome, the third dataset was generated using an error profile from a poorly sequenced sample.

Overall, concordance accuracy improved with increase in sample coverage (Figure 2), and the proportion of positions that could not be identified by any variant caller decreased with increase in coverage (Supplementary Figure 1). For all the three datasets, and at each coverage level, fully concordant variants were below 50% of the total variants suggesting that considering only fully concordant positions eliminated a substantial number of variant positions. There were marginal improvements in the number of concordant variants in the second dataset compared to the first and the third error profile. Across all datasets, there was little improvement at detecting fully concordant positions after a coverage of 2000 (Figure 2).

FreeBayes identified majority of the variants (Figure 3) across all the datasets although it was characterised by variable sensitivity and precision (Figure 4) in addition to a high false positive rate (Table 3) relative to the other minority variant callers depending on the sample coverage. This was observed across all the three datasets. Lofreq was the most conservative of the callers and it missed majority of the variants across all the three datasets. In addition, Lofreq’s sensitivity did not increase with increased coverage (Figure 4). We utilized UpSetR plots to provide a visual summary of the combination of variant callers that contributed to the observed concordance accuracy (Supplementary Figure 2).

**Figure 2.** Proportion of fully concordant positions with respect to sample coverage. Each plot A–C represents the proportion (y-axis) of fully concordant variants with respect to read coverage (x-axis) for the first, second and third dataset. Concordant positions were defined as positions that were identified by all the four variant callers.
Figure 3. Heat maps illustrating tool specific concordance for the first artificial dataset. The red tiles represent variants detected by each caller from the list of 166 variant positions. The panels are arranged left to right A–H in the order of increasing sample coverage (20,50,100,500,1000,2000,5000 and 10,000). The “not called” column in each panel represents the variants that were not identified by any of the variant callers.
A summary of the relationship between sample coverage, sensitivity (A–C) and sample coverage and precision (D–F). The x-axis shows the sample coverage and the y-axis represents the sensitivity and precision respectively. Sensitivity of the callers rose gradually from low to high coverage samples with the exception of FreeBayes which showed variable sensitivity for samples with different coverage. Again, precision was variable for FreeBayes calls while relatively high for the rest of the three callers.
Discussion

Detecting and reporting minority variant calls is challenging, given that low frequency calls occur at similar frequency as sequencing and PCR errors. Recent studies have linked the sharing of minority variants with transmission patterns, and hence it is important to ascertain actual minor variants from spurious variant calls. Several minority variants callers use different detection algorithms and statistics, each of which attempt to optimize an aspect of the variant calling process. Therefore, there could be disparities between what is reported by a given minority variant caller, given datasets of varying sequencing depths and error profiles.

This study aimed to identify the proportion of positions that were recognized as minority variants by a set of tools using three artificial datasets of varying coverage and error profiles. Concordance accuracy and inter-caller concordance measures were dependent on the sample coverage and error profile. Sensitivity for majority of the tools was positively correlated with depth of coverage. This was similarly observed by Spencer et al., (Spencer et al., 2014) in a study that investigated performance in methods used to detect low-frequency variants. In the first artificial dataset, VarDict detected true positive variants with comparably good performance (sensitivity 43.4% – 72.3%), though it was marginally invariant to changes in average coverage above 20. VarDict has in-built features that could contribute to its efficient performance. It is able to activate an “amplicon calling mode” that filters out amplicon biased variants and mispaired primers as PCR artefacts. A similar pattern was observed with LoFreq, where sensitivity was not significantly affected by depth of coverage. VarScan2 was more affected by coverage and maintained average sensitivity (6.6% – 58.4%). Applying filters in VarScan has been reported to improve sensitivity by reducing number of false positives (Hofmann et al., 2017; Koboldt et al., 2013). FreeBayes’ trade-off between sensitivity and precision was also reported by other studies (Hwang et al., 2015; Sandmann et al., 2017).

Based on artificial reads from the second dataset, FreeBayes performed comparatively better than the other tools (Figure 3). This suggests that FreeBayes is potentially useful in identifying minority variants when sample data comes from reads with a low error profile. This implies the error rate results are outcome of tool performance.

Specificity of a caller is its ability to correctly predict the absence of a minority variant. The variant callers make use of a high specificity to minimize the number of false positive calls thereby reducing post-call filtering and consequently filter out true low-frequency variants. Moreover, high accuracy measures demonstrate the reliability of the variant caller in correctly identifying true variants.

In absence of an explicit error model from samples of heterogeneous sequencing quality, combining at least three tools when identifying minority variants could potentially assist in filtering out errors from low frequency variants. Given that there are no definitive data and next generation sequencing pipeline standards for minority variant calling approaches that are specific for viruses, there are opportunities to develop robust methods and tools that strike a balance between detecting errors and true minority variants from field virus samples that present with different sequencing quality.

Data availability

The data analysis scripts and datasets used in analysis are available from our institutional Dataverse repository: http://dx.doi.org/10.7910/DVN/ZIO43M (Mohammed & Githinji, 2018)

Data are available under the terms of the Creative Commons Attribution 4.0 International license (CC-BY 4.0).

Supplementary File 1: A description of data generation methods and command line tools used to create the artificial datasets. Click here to access the data.

Supplementary File 2: FastQC metrics for sample used to generate simulated reads for the second dataset. Click here to access the data.

Supplementary File 3: FastQC quality profile for sample used to generate simulated reads for the third dataset. Click here to access the data.

Supplementary Figure 1: Proportion of fully concordant positions with respect to sample coverage in dataset1. (A) Represents the proportion (y-axis) of fully concordant variants with respect to read coverage (x-axis) and B) shows the proportion of variants positions that could not be identified by any minority caller at each level of sample coverage. Click here to access the data.

Supplementary Figure 2: UpSetR plots showing the concordance between called variants and the respective variant callers using the first artificial dataset. The intersection size illustrates the number of variants in each intersection set. The horizontal axis shows the combination matrix identifying the intersections. A single filled circle represents a unique set of variants. Connected lines depict shared variants (intersections) among the variant callers. Intersection size was positively correlated with average coverage at (a) 20X, (b) 50X, (c) 100X, (d) 500X, (e) 1000X, (f) 2000X, (g) 5000X and (h) 10,000X. Click here to access the data.

This is a comparative review of variant calling tools with focus on the detection of minority variant calls, specifically with reference to virus data. The authors have provided data on four freely available tools that can be tuned to call minority variants, or are specifically designed for this purpose. The data used here was artificial reads generated with the ART-Illumina tool, which were spiked in with variants at known locations. This was replicated eight times at levels of read coverage spanning four orders of magnitude. The outcome of the experiment was a low level of concordance between tools. None of the tools were able to identify all of the spiked-in variants.

The approach taken here is technically sound, as it is based on a strictly defined truth set, although I am slightly uncomfortable with the lack of real data (but equally I am aware of the methodological problems real data presents in this kind of scenario). The study is useful for the wider community as a) it reiterates the point that using a single tool for a given bioinformatics task comes with the risk of missing information and b) it provides concrete pointers as to which tools perform well in this scenario.

My main reservation is that there is no mention of the importance of parameter settings. Different parameter values can affect variant calling outcomes dramatically, even when just comparing different runs of the same tool. FreeBayes alone has over 70 command line parameters, many of these continuous variables. This makes for an incredibly large parameter space, and using different sets of parameter values can potentially have much more of an impact on the results than the choice of tool. This should at least be mentioned in the Discussion section.

There also doesn’t seem to be any data on how the individual tools were parameterised in this study. Were the defaults used in each case? Presumably not, given that we are looking for minority variants (and tools like FreeBayes appear to be developed and parameterised with a human germline use case in mind). This information is critical for reproducibility and must be included (even if it is just a statement saying the defaults were used).
My other comments below reference the online PDF version of the article.

Abstract
- Results section: change “FreeBayes identified majority” to “FreeBayes identified the majority”
- Conclusions section: change “impact” to “impacts”

Introduction
- para 1 line 7: is the “and” redundant?
- para 5 line 7: comma after “callers”

Methods
- para 1 line 1: “we considered eleven published, open-source tools” I counted six excluded tools in Table 1, plus four that have been taken through to evaluation = 10
- para 2 (“Artificial datasets”): The concept of the error profile has not been well explained. This section needs to be expanded. I would like to see some description of what the error profile consists of, how it has been derived from the FASTQC data, and how it has been applied to the reads in practice.
- para 3 line 2: “at varying frequencies” – what were they? I presume we are talking about the proportion of reads at a spiked-in variant site that carried the alternate allele at this site. This information strikes me as absolutely critical for this paper – this is about minority variants after all. Please provide this data.
- para 4 line 8: “written as a comma separated (CSV) files” should be “written as a comma separated (CSV) file”

Results
- para 3 line 1: “FreeBayes identified majority” should be “FreeBayes identified the majority”
- para 3 line 7: “it missed majority” should be “it missed the majority”
- General comment: Vardict should get a mention in this section, as it actually had better recall rates than FreeBayes in 6 out of 8 samples.

Discussion
- para 1 line 5: change “ascertain” to “distinguish”
- para 3 line 1: “Sensitivity for majority” should be “Sensitivity for the majority”

Table 3
- As far as I can tell, the counts for FN + TP should always add up to 166. This is not the case for the majority of the Freebayes runs (except for Freebayes with samples 1 and 3, which are ok).

Supplementary File S1
- To ensure reproducibility, please include the BAMSurgeon command line statement for spiking in the variants.

Supplementary Figure 2
- It is not apparent what the individual figures/pages in the PDF file represent. Please label these appropriately.

Is the work clearly and accurately presented and does it cite the current literature?
Yes
Is the study design appropriate and is the work technically sound?
Yes

Are sufficient details of methods and analysis provided to allow replication by others?
Partly

If applicable, is the statistical analysis and its interpretation appropriate?
Yes

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Yes

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 13 Aug 2018

George Githinji, KEMRI-Wellcome Trust Research Programme, KEMRI Centre for Geographic Medicine Research – Coast, Kilifi, Kenya

We are grateful for taking time to review this work and for providing useful comments that we have considered in this new draft of the manuscript.

- We agree on the challenges of obtaining and using the appropriate actual data when conducting these types of analysis. We have done our best to generate reliable artificial datasets based on an actual RSV reference genome and error profiles from two sequenced samples using the methods described in this manuscript.
- In regard to the importance of parameter settings and lack of data on how individual tools were parameterized, we have explicitly stated the parameter settings in the variant calling section and in the Supplementary File 4. In the discussion section, we highlight the challenge of exploring all possible parameter settings.
- The concept of the error profile has is now well explained in paragraph 1 of the artificial datasets section in the current manuscript.
- The actual frequencies used to spike the variants are now described and provided in Supplementary file 5.
- There was a bug in the script used to calculate the FN and TP counts in FreeBayes runs. This has been corrected and updated to reflect the true FN and TP counts. A revised table and subsequent figures have been provided.

Competing Interests: No competing interests were disclosed.

Reviewer Report 22 March 2018

The authors validate methods to call low frequency minority variants from viral samples. Detection of minority species in viral population sequencing helps improve treatments by matching drugs to the full spectrum of sub-species, and allows tracking of sub-species within outbreaks.

The paper uses synthetic datasets generated by the ART read simulator (https://www.niehs.nih.gov/research/resources/software/biostatistics/art/) with randomly generated variants. While this won't fully describe the complexity of a real viral mixture, it does provide a solid baseline for assessing callers. The authors used mutation error profiles from good and bad sequencing samples to model different error rates, and evaluated the impact of differing coverage on sensitivity and specificity.

My main suggestion is to stratify comparisons by variant frequency to assess how callers do with different low frequency events, and I provide more specific comments below.

Methods suggestions

- The stratifications by coverage, error rates and callers are great for identifying the effect of different callers on detection. The one missing component is the allele frequency of the generated variants. The paper does not define the range of frequencies generated, and this will have a large impact on the ability of detection across callers. Looking through the list of generated variants (Githinji_2018_variant.list.tab) the range varies from high frequency (90%+) to very low frequency (<1%). Since the focus is on low frequency detection, I'd suggest stratifying the results into bins: standard (>25%), moderately low frequency (5-25%) and low frequency (<5%) and examine the caller and depth detection within these bins. Pending the results of this, the authors may want to generate additional low frequency variants to help differentiate caller methods.

- A confusing aspect of evaluating the depth metrics is that the number of possible true positives differs between sample depths. In Table 3, the FreeBayes TP + FNs are 166, 165 and 166 for 20x, 50x and 100x. However they change to 61, 55 and 55 for 500x, 1000x and 200x. Other callers seem to be consistent. Why does FreeBayes have different total variant numbers across depth?

Paper suggestions

- Table 1 should get compressed into a single paragraph saying that HaploptotypeCaller, Platypus and mpileup target germline calling and not low frequency detection. It doesn't need to be a separate table.

- Table 2 should be replaced into a link to descriptions of true/false positives/negatives and does not need to be a separate figure in the paper.
The title should reflect that this paper describes viral calling (versus, say low frequency somatic variant detection).

Is the work clearly and accurately presented and does it cite the current literature? 
Yes

Is the study design appropriate and is the work technically sound? 
Yes

Are sufficient details of methods and analysis provided to allow replication by others? 
Yes

If applicable, is the statistical analysis and its interpretation appropriate? 
Not applicable

Are all the source data underlying the results available to ensure full reproducibility? 
Yes

Are the conclusions drawn adequately supported by the results? 
Yes

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 13 Aug 2018
George Githinji, KEMRI-Wellcome Trust Research Programme, KEMRI Centre for Geographic Medicine Research – Coast, Kilifi, Kenya

We are very grateful for taking time to review this work and for providing useful comments which we have considered in the new version of the manuscript:

• All the paper suggestions have been considered table 1 and table 2 were removed and replaced with text descriptions.
• We have added a new figure comparing the allele frequency of the spiked and called variants. We highlight the observations in the result and discussion sections. In addition, we provided a stratified result of the variants frequency and discuss how the callers perform for different low frequency events. We also provided an addition set of spiked variants at frequency below 50%.
• The results section in table 3 have been revised to reflect the correct number of TP and FN for FreeBayes. Figure was also revised to reflect the new changes.

Competing Interests: No competing interests were disclosed.
