Abstract

Policymakers in Africa need robust estimates of the current and future spread of SARS-CoV-2. We used national surveillance PCR test, serological survey and mobility data to develop and fit a county-specific transmission model for Kenya up to the end of September 2020, which encompasses the first wave of SARS-CoV-2 transmission in the country. We estimate that the first wave of the SARS-CoV-2 pandemic peaked before the end of July 2020 in the major urban counties, with 30-50% of residents infected. Our analysis suggests, first, that the reported low COVID-19 disease burden in Kenya cannot be explained solely by limited spread of the virus, and second, that a 30-50% attack rate was not sufficient to avoid a further wave of
transmission.

Keywords
SARS-CoV-2, Kenya, dynamic model, serology, PCR cases

Introduction

The potential risk from severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) to Africa was identified early in the global pandemic. As the epicenter of transmission moved from East Asia to West Asia and Europe and then to North America, there was speculation as to the likely impact of the pandemic on the African continent with its young populations, high infectious disease burden, undernutrition and fragile health infrastructure. However, as health systems and economies of high-income countries strained, the reported burden of COVID-19 cases and associated deaths in Africa remained low with the exception of South Africa and Northern Africa. The question is whether this is the result of lower risk due to demographic structure (young age), either cross-reacting immunity (e.g. pre-existing SARS-CoV-2 cross-reactive T cells) or dampened immunological over-reaction, a low reproduction number from rapidly imposed interventions (such as school closures and lockdowns), environmental conditions (e.g. temperature and humidity), or under-reporting. The reason this remains a conundrum is, at least in part, a paucity of good quality data to reveal the probable extent of SARSCoV-2 spread in African populations.

Following the first confirmed coronavirus disease 2019 (COVID-19) case in Kenya on 13th March 2020, the Kenyan Government moved rapidly, closing international borders, schools, restaurants, bars and nightclubs, banning meetings and social gathering, and imposing a dusk to dawn curfew and movement restrictions in the two major city counties, Nairobi and Mombasa. The major concerns from unmitigated spread were a limited surge capacity of the Kenyan health system and groups of the Kenyan population identified as potentially highly vulnerable to infection, due to socio-economic factors such as crowded households or lack of access to handwashing, and/or severe disease, due to epidemiological factors such as higher rates of obesity and hypertension. Throughout the months of April, May and into June 2020, few people in Kenya were reported SARS-CoV-2 test positive by polymerase chain reaction (PCR), or severely diseased or dying with COVID-19 as the established cause. There followed a relaxation of some measures in June and July including controlled opening of restaurants and places of worship and the removal of travel restrictions into and out of Mombasa and Nairobi counties. As of 30th September 2020, there were 45,795 laboratory-confirmed cases in Kenya, with 1,310 fatalities. The country has recorded over 800,000 recoveries, with 42,000 new cases in the last week alone.

The reason for this apparently low level of COVID-19 disease in Kenya is unknown; one possible explanation is that SARS-CoV-2 had not widely spread among the Kenyan population by the end of September. However, two pieces of information suggest that SARS-CoV-2 had al-ready spread extensively by the end of September. First, a regionally-stratified seroprevalence study of 3098 Kenyan blood donors sampled between May and June reported a national estimate of 4.3% (adjusted to reflect the population distribution by age, sex and region). Sero-prevalence was higher in Nairobi (7.6%) and Mombasa (8.3%). These levels of seropositivity are comparable to those reported in May in the United Kingdom (UK), April/May in Spain, and March/April in some United States (US) cities, where high numbers of PCR-positive cases, hospitalizations and deaths have also been reported, in contrast to Kenya. Second, we noticed that test-positive PCR cases, and daily reported test-positive deaths, were declining in first Mombasa (from early July 2020) and then Nairobi (from early August 2020); respectively Kenya’s second and first largest cities. In Europe, declining case and mortality rates have been closely associated with non-pharmaceutical interventions (NPIs). However, in Kenya this went counter to evidence of increased mixing, and hence reproduction potential, arising from Google Mobility data for these cities which showed a steady reversion in mobility towards pre-COVID-19 intervention levels since early April (Fig. S1). These observations, in turn, lead to the conclusion that either a smaller than expected proportion of infected individuals had had severe disease, and/or, that there has been under-reporting of severe disease.

To investigate these findings, we developed a simple SEIR (susceptible-exposed-infectious-recovered) compartmental mechanistic and data-driven transmission model for Kenya, which integrates three sources of longitudinal data: national time series polymerase chain reaction (PCR) tests, the Kenyan serological survey and Google mobility behavioural data. The overall modelling approach is similar to Flaxman et al.; that is we use time-to-event lag distributions, and the daily incidence time series, and, both models generate the daily incidence time series using a simple deterministic transmission model with the key unknowns being initial numbers of infected individuals and R(t). Where we differ in approach from Flaxman et al. is that, instead of using reported test-positive deaths as the most reliable data for inferring underlying transmission patterns, we use a combination of PCR test-positive and serological data. The PCR test-positive data informs the model on the epidemic trajectory but does not account for likely under-detection of cases. This under-detection of cases is inferred from the proportion exposed to SARS-CoV-2 evidenced by the seroprevalence estimates, hence scaling the incidence estimation. Finally, the mobility data, as a proxy for the contact rate, determines the contribution of the intervention (which acts to alter contact patterns) relative to other factors that alter incidence and the effective reproduction number, the most important of which is the susceptible proportion of the population. Our aim is to derive a coherent picture of the SARS-COV-2 epidemiology in Kenya in the first wave and reveal the historic and future patterns of spread across the country and by county. Reported deaths are not used as primary data for inference, but rather the trend in changing rates of reported deaths is used as a validation data set for model predictive accuracy (see supporting information for description of model validation). Reported deaths may be subject to substantial under-reporting, and we assume that the bias in under-reporting is consistent over time.
Results
Underlying transmission rates in Mombasa and Nairobi during the first wave
As at 30th September, a substantial proportion of PCR positive tests have been samples from the capital Nairobi (25,182 positive tests), while Kenya’s second largest city, Mombasa, has reported the next highest number of PCR positive tests (2,056). We infer that the underlying rate of new infections peaked on May 18th 2020 (CI May 16th - May 21st) in Mombasa and July 9th 2020 (CI July 7th - July 10th) in Nairobi, and subsequently declined from peak transmission (Figure 1 H, G). The model suggests that the PCR test and serology data can be explained by the initial presence of <200 infected individuals in both Mombasa and Nairobi on 21st February, three weeks before the first reported case in Kenya. Thereafter, growth of transmission was rapid in both counties. In early March, the reproductive ratio was estimated to be 1.94 (CI 1.89-1.98) and 2.00 (CI 1.97-2.02) in Mombasa and Nairobi, respectively, with associated doubling-time of 4.84 and 4.59 days, respectively. After March, the transmission curves flattened substantially. This change is consistent with the introduction of containment measures by the Kenyan government, and evidence of substantial reduction in mobility (see Google Mobility data Fig. S1). From late April, through May and June, and into July the evidence suggests movement restrictions became steadily less effective. The waning effectiveness of movement restrictions results in an inferred increase in R(t) across Kenyan counties and an increased rate of epidemic growth (Figure 2). The increasing R(t) estimates are broadly in line with predicted trends from Google mobility data (supporting information), although it should be noted that the R(t) estimates exhibit secondary fluctuations around the increasing mobility trend (Figure 2). In Nairobi and Mombasa we predict that reduction in susceptibility of the population (Figure 1C,D) caused the effective reproductive ratio (R_eff, t) to drop significantly below the basic R value from June onwards (Figure 2). However, other counties, where the epidemic did not establish itself as early as Mombasa and Nairobi, and where a substantial majority of the population are likely to still be susceptible, now have R(t) estimates which we estimate rebounded to the original levels estimated as occurring before Kenyan public health measures (Figure 2).

By accounting for the delay of an average of 19 days between infection and death (supporting information for details on infection to death distribution) we find the transmission curve, estimated from PCR tests and serology, generates a good prediction of the observed trend in daily deaths in Nairobi and Mombasa (Figure 1 E, F). We did not use mortality data in transmission model inference, therefore the good fit to the observed trend in deaths with a PCR-confirmed test result represents an out-of-sample validation of the modelling. Note, it is the distribution of deaths over time, rather than the absolute numbers, that we consider to be a good fit. In accord with observations, we estimate a peak of positive PCR test samples occurred at the end of July or early August in Nairobi and earlier, mid-June, in Mombasa. The lag between transmission peak and positive swab testing peak being explained by both the delay between infection and becoming detectable by PCR, and the period after an infected individual has ceased being actively infectious but remains detectable by PCR (Figure 1 G,H and A,B). As of the end of September 2020 we estimate that about 35.4% (CI 29.0%-40.4%) of the Nairobi population, and 30.3% (CI 23.6%-36.7%) of the Mombasa population were serologically positive with SARS-CoV-2, (Figure 1 C,D). This estimated level of seropositivity is substantially higher than has been estimated in some countries that have been hit hard by the pandemic. However, they are in broad agreement with a study in Niger state, Nigeria, from June 2020, as well as seropositivity rates reported from the hard-hit city of Manaus, Brazil, in May 2020. Note that these estimates of seropositivity at the end of September assume both that waning seropositivity would not have had a significant effect on serological observations by late September, and furthermore that waning immunity leading to re-infection remained insignificant by late September.

SARS-CoV-2 attack rates in the first wave in Kenyan counties and the estimated crude infection-to-fatality ratio
Accounting for the sensitivity of the serological assay, and the delay between infection and seroconversion, we estimate that the actual exposure of the population to SARS-CoV-2 by September 30th was 43.3% (CI 35.3%-49.5%) in Nairobi and 37.6% (CI 29.2%-45.7%) in Mombasa (Figure 1 C,D). Such levels of population exposure are predicted to be associated with decreased rates of new cases due to reduced numbers of susceptible individuals in these urban populations, although this is also influenced by the estimated reproductive number and effective population size at risk of exposure (P_e). The effective population size accounts for the impact of heterogeneity in the susceptibility, transmissibility and social interactivity in the population (supporting information for more details on effective population size in transmission modelling); for Nairobi it was inferred as 81.8% of actual population size (CI 66.7%-93.2%), for Mombasa 71.9% (CI 56.3%-86.5%). The effective population size estimates rest upon inferred variation in risk across the population. There remains a possibility of future increase in transmission if population mobility continues to rise, if population mixing patterns alter leading to changed risk heterogeneity or if immunity is short lived, leading to a rebound in reported cases. One or more of these factors could lead either to lengthening the tail after the first peak in cases/deaths, or even to a secondary increase in cases and/or deaths.

The inferred IFR_crude values for both Nairobi (IFR_crude = 0.019% (CI 0.014%-0.024%)) and Mombasa (IFR_crude = 0.022% (CI 0.016%-0.027%)) are substantially lower than the age-adjusted IFR expected for Kenya under full ascertainment from the age-specific IFR estimated given by Verity et al. (IFR_age = 0.26%22; and supporting information). This is a crude observational value for the infection to fatality ratio, since we do not currently have an estimate of the reporting bias of deaths of individuals infected with SARS-CoV-2. Therefore, our estimate of IFR_crude potentially reflects lower detection in
Figure 1. SARS-CoV-2 PCR positive swab tests, seroprevalence and deaths in Nairobi and Mombasa, Kenya, with model forecasting. Kenya compared to China, as well as any lower mortality risk due to fewer comorbidities.

We extended our model-based inference to each of the 47 counties in Kenya (see dataset S1 for parameter estimates, peak time estimates and IFR crude estimates for each county). We find that, in addition to the two main Kenyan city counties, more than 25–30% of the population in each of the semi-urban counties neighbouring Nairobi (Kiambu, Kajiado, and Machakos) had been infected. However, the infection rate is predicted to be either lower than 25% and/or subject to high uncertainty in other counties (with high uncertainty defined as a prediction standard error of > 10% of county population size; Figure 3).

Due to the lag between infection and the observability of the infected person (whether by swab PCR test, serology test, or death), we estimate that both daily PCR positive test detections and daily observed deaths attributed to COVID-19 across the two main cities, and semi-urban counties neighbouring Nairobi had a peak in early August 2020 (Figure 3 B,C). Hospitalisation rates are not available for all Kenyan hospitals. However, sentinel clinical surveillance of severe acute respiratory infection (SARI), with or without a PCR test for SARS-CoV-2, at 14 county hospitals suggests an increasing rate of adult admissions in June and July 2020. However, SARI admissions were lower in the early phase of the Kenyan epidemic than observed counts from the same months in 2018 and 2019 and the apparent rise in SARI admissions could represent a reversion towards pre-COVID numbers; this observation underlines the difficulties in using hospital data to understand the penetration of SARS-CoV-2 in Kenya.

Conclusions and Discussion

Our modelling analysis provides a coherent account of the SARS-CoV-2 pandemic in Kenya up to end September 2020. Limitations include lacking information on the PCR testing denominators for the full time frame, the limited serological survey and that we have applied a simple dynamic model. In mitigation similar results were obtained when excluding all negative tests, and the dynamic model is transparently fit to the data where the availability of the latter is a key strength of our study.

Our analysis suggests that 30–50% of the urban population were already exposed by the end of September, and that the first wave of the Kenya epidemic peaked in the urban and semi-urban counties during a period of relatively little restrictions or physical distancing. This infers a burden of infection in Nairobi and Mombasa similar to extremely hard-hit cities in South America at the same time, e.g. Manaus. However,
Figure 3. Predicting peak timing of transmission rate by Kenyan county, and forecasting of Kenya-wide PCR positive swab tests and reported deaths. (A) Posterior mean estimates for the attack rate (% of population) in each county. Solid shaded counties have a posterior standard deviation in their attack rate estimate of less than 10%, candy-stripe shaded counties have greater uncertainty associated with their attack rate estimate. (B) Kenya total positive swab tests collected by day of sample (blue dots) with model prediction of daily positive swab test trend (red curve). (C) Kenya total reported deaths with a positive swab test (black dots), with model prediction of reported death rates (black curve). Inset plot indicates cumulative reported deaths with model prediction of cumulative deaths. Dates on (B) and (C) mark 1st of the month.
in Manaus there was a substantial first epidemic wave through April-June 2020, with about 50% of the population infected, followed by a long epidemic tail leading to an estimated total 75% attack rate by the end of 2020\cite{ref31}. In Kenya, the second wave came shortly after the first (October to December 2020), which suggests that the causes of the Kenyan second wave are complex.

Whilst the full picture of the epidemiology in Kenya will not be established until cause-specific mortality data become available (e.g. from resumption of Demographic Surveillance System and verbal autopsy activities), our model, fitted to three sources of nationwide longitudinal data, suggests that the number of symptomatic COVID-19 cases reported and the mortality attributed to the SARS-CoV-2 epidemic are substantially lower in Kenya than in Europe and the USA at a similar stage of the epidemic. This would remain the case even if reported deaths accounted for just 1/10th of the true value. However, there is insufficient data for speculating on the degree of under-reporting and previous estimates of 1 in 4 deaths occurring in hospital may not be generalizable to the hospital access during the COVID-19 pandemic\cite{ref31}.

Late 2020 saw the spread of COVID-19 to more rural areas of Kenya, with less infrastructure and access to public health facilities and a second wave of SARS-CoV-2. This second wave needs to be dissected and understood. Policy makers need to balance the direct and indirect health and socio-economic consequences of any control measures; a balance that becomes more precise as we develop a better understanding of SARS-CoV-2 dynamics in Kenya.

**Methods**

**Transmission model definition**

The dynamics of transmission in each Kenyan county were assumed to follow a SEIR transmission model with an effective population size parameter ($P_{\text{eff}}$)\cite{ref25}. The SEIR model with effective population size is an extension of the homogeneous SEIR model\cite{ref26} with the additional flexibility that $P_{\text{eff}}$ out of a total population size $N$ in each county is at risk of contracting SARS-CoV-2. $P_{\text{eff}}=1$ recovers the homogeneous SEIR model, whereas, $P_{\text{eff}}<1$, recovers the effect of underlying heterogeneity in the transmission potential and risk in the population of the county on the aggregate dynamics of epidemic. This aspect of heterogeneous models of transmission has been widely investigated, for example, in the context of comparing vaccination coverage thresholds for elimination between uniform and targeted vaccination policies\cite{ref27}. In the context of the SARS-CoV-2 pandemic modelling literature, the possible role of population heterogeneity in decoupling estimates of $R_t$ from predictions of the “herd-immunity” threshold and final attack rate has again been identified\cite{ref28,ref29}. In this study, rather than make strong assumptions about the mechanism of population heterogeneity, e.g. differential susceptibility, differential rates of social mobility etc., we have taken a phenomenological approach; the effect of heterogeneity in the population was encoded in the effective population parameter $P_{\text{eff}}$ and this parameter was inferred jointly with $R_t$. Our *a priori* belief was that the most probable value was $P_{\text{eff}} = 1$. We assumed that $P_{\text{eff}}$ was constant over the period of inference.

The model dynamics for each Kenyan county were represented as a system of ordinary differential equations,

\[
\begin{align*}
\dot{S}(t) &= -\gamma R_t \frac{S(t)I(t)}{P_{\text{eff}} N}, \\
\dot{E}(t) &= \gamma R_t \frac{S(t)I(t)}{P_{\text{eff}} N} - \sigma E, \\
\dot{I}(t) &= \sigma E(t) - \gamma I(t), \\
\dot{R}(t) &= \gamma I(t), \\
\dot{C}(t) &= \gamma R_t \frac{S(t)I(t)}{P_{\text{eff}} N}.
\end{align*}
\]

(1)

With initial conditions (time 0 is the calendar date 21st Feb 2020 and all rates are per day),

\[
\begin{align*}
S(0) &= P_{\text{eff}} N - E_0 - I_0, \\
E(0) &= E_0, \\
I(0) &= I_0, \\
R(0) &= 0, \\
C(0) &= 0.
\end{align*}
\]

(2)

Where the dynamic variables $S(t)$, $E(t)$, $I(t)$, $R(t)$ were the numbers of susceptibles-at-risk, exposed (but not yet infectious), infectious, and, recovered individuals in the county. The full number of susceptibles in the county at any time was $(1 - P_{\text{eff}})N + S(t)$. $C(t)$ was the cumulative numbers of infected individuals in the county.

The incubation-to-infectious rate was $\sigma = 1/3.1$ per day, and the recovery rate was $\gamma = 1/2.4$ per day, implying a mean generation time of 5.5 days (see Supporting information for a comparison to the generation distribution inferred by Ferretti et al.\cite{ref28}). The instantaneous reproductive ratio $R_t = R_t \beta$, decomposed into a basic reproductive ratio $R_0$ and an effective contact rate $\beta$, where $\beta = 1$ represents a pre-pandemic baseline contact rate in the population.

**Transmission model inference**

We used a mixed Bayesian and maximum a-posteriori (MAP) approach to parameter inference for each of the 47 Kenyan counties, based on daily observations of positive and negative PCR and serological tests in each county. The probability of individuals being detectable on any given day was based on whether they had been infected before that day, and, the number of days since their infection. The number of new infections on each day $n$, was denoted $I_n$. For a given set of model parameters $t_n$ was generated by solving the ODE system (1), giving,

\[
t_n = C(n+1) - C(n),
\]

(3)

for each day $n$. Given the daily numbers of new infections, the number of people in the county on each day $n$ who are detectable by PCR testing, denoted $(P')_n$, and serological testing, $(S')_n$, were given by convolving the new infection time series
with the probability of (respectively) being detectable by a PCR or serological test \( t \) days after infection, \( Q_{\text{PCR}}(t) \) and \( Q_{\text{sero}}(t) \):

\[
(P^+)_n = [1 * Q_{\text{PCR}}](n),
(S^+)_n = [1 * Q_{\text{sero}}](n).
\]

The log-likelihood function for each county has the form,

\[
l((P^+)_1,...,(P^+)_T,(S^+)_1,...,(S^+)_T, \theta_{\text{OM}}) =
\sum_n \ln f_{\text{PCR}}((\text{Obs})^+)_n | (P^+)_n, \theta_{\text{OM}}
+ \ln f_{\text{sero}}((\text{Obs})^+)_n | (S^+)_n, \theta_{\text{OM}}.
\]

Where, \( f_{\text{PCR}}((\text{Obs})^+)_n | (P^+)_n, \theta_{\text{OM}} \), and, \( f_{\text{sero}}((\text{Obs})^+)_n | (S^+)_n, \theta_{\text{OM}} \), were, respectively, the log-probability of observing \((\text{Obs})^+\), PCR test-positives and \((\text{Obs})^+\), serological test-positives on days \( n = 1, ..., T \) given the model prediction of numbers of PCR and serological detectable people in the population, and the observation model parameters \( \theta_{\text{OM}} \). Day \( n = 1 \) corresponded to the calendar date 21st February 2020, and, day \( n = T = 223 \) corresponded to 30th September 2020. The observation model parameters included bias and over-dispersion parameters for finding PCR positives in the daily testing group compared to an unbiased binomial sample over the population; we used a beta-binomial count data model whenever the number of negative PCR tests for that day was available in the county and a negative binomial count data model whenever it was not. We assumed that the serological test-positives were from an unbiased sample but included over-dispersion in sampling serological positives by using a beta-binomial count data model. Supporting information gives further details on the data sources and the log-likelihood calculation including a full description of all observation model parameters and the functional forms and underlying evidence for \( Q_{\text{PCR}} \) and \( Q_{\text{sero}} \). The data sources used were: The Kenya Ministry of Health National linelist, the Kenya Medical Research Institute Wellcome Trust Research Programme (KEMRI-WTRP) serological surveillance programme and Google mobility data. The full Kenyan SARS-CoV-2 line list contains sensitive personal information that could potentially allow the identification of individual cases. The analysis performed in this study only required an aggregated dataset derived from the Kenyan linelist. Other data used in this paper was openly available. All data is available in the main text or as underlying data.

We assumed that \( \beta_t \) was piece-wise constant on days, and, therefore, could be reconstructed from daily effective contact rates \((\beta_t)_{t=1,...,T}\). For any fixed estimate of the effective contact rate \( \beta_t \), we used Hamiltonian Markov-chain Monte Carlo (HMC) to estimate the posterior distribution for the transmission model parameters; that is the initial condition values \((E_0, I_0)\) and fixed parameters \((P_{ef}, R_0)\) jointly with the observation model parameters \( \theta_{\text{OM}} \). Prior distributions for parameters were chosen for groups of counties (e.g. largely rural counties had different priors to major urban conurbations like Nairobi and Mombasa; see supporting information for further details). Starting from an initial estimate that \( \beta_t \) followed daily Google mobility trends for the whole period, we sequentially improved our \( \beta_t \) estimate using the expectation-maximisation (EM) algorithm. The E-step corresponding to posterior distribution estimation using HMC, and the M-step corresponding to optimising the daily effective contact rate estimates \((\beta_t)_{t=1,...,T}\) using the popular stochastic gradient descent algorithm ADAM. The first 40 days of effective contact rate estimates \((\beta_t)_{t=1,...,40}\) were assumed to be fixed to their Google estimate; this improved identifiability jointly with \( R_0 \) and captured the observed sharp drop in mobility in response to Kenyan public health measures following the first identified case on 13th March 2020. See supporting information for further details on the use of Google mobility data and the EM algorithm method used in this study.

After inference of transmission parameters, the model implied a prediction of the expected number of daily deaths due to COVID, \( \mathbb{E}(X^-) \), based on an overall population infection-to-fatality ratio (IFR), and, the delay distribution between infection and death, \( p_{\text{delay}} \).

\[
\mathbb{E}(X^-)_n = \text{IFR}(t * p_{\text{delay}})(n).
\]

In this study, we assume that the IFR is constant for each county over the period of inference, which allows us to construct a Bayesian estimator of the crude IFR, \( \text{IFR}_{\text{crude}} \), by fitting to the observed daily numbers of test-positive deaths, \((\text{Obs})^-\), (see supporting information for details and background data informing \( p_{\text{delay}} \)). Because the observed test-positive deaths were not used in inferring model parameters, we treat the log-predictive density of deaths from the model as an out-of-sample validation metric for the model. However, we emphasise that the out-of-sample comparison is to the trend of daily deaths, because this is invariant to the \( \text{IFR}_{\text{crude}} \) estimator, which is itself sensitive to under-reporting of COVID deaths. Supporting information gives full details on the Bayesian model validation used in this study.

This study was approved by the Kenya Medical Research Institute Scientific and Ethics Review Unit (KEMRI-SERU) with approval numbers KEMRI/SERU/CGMR-C/203/4085 and KEMRI/SERU/CGMR-C/203/3426 for the modelling and serosurvey studies respectively.

Data availability

Underlying data

Zenodo: Revealing the extent of the first wave of the COVID-19 pandemic in Kenya based on serological and PCR-test data. https://doi.org/10.5281/zenodo.4705244 This project contains the following underlying data:

- Data S4 (The number of positive, and negative where available, PCR-confirmed swab tests for each county by date of sample collection (21st Feb to 30th September)).
Data S5. (The number of positive and negative serological results for each county by date of sample collection (21st Feb to 6th August)). This is from the Kenyan Ministry of Health National linelist.

Data S6. (The number of deaths with a PCR-confirmed swab test for each county by recorded date of death (21st Feb to 30th September)).

Data S7. (Summary data of Kenyan epidemic, including reported total number of test performed in Kenya.

supp material.docx (A more detailed description of the data).

Software availability
The analysis code was written in Julia language version 1.4.

The code base underlying the analysis is accessible at the open github repository https://github.com/ojal/KenyaSerology. For the analysis presented here we developed a module in the Julia programming language called KenyaSerology. Tutorial notebooks for running KenyaSerology and analysing the underlying data are available in the repository.

25. Li M, Dushoff J, Bolker BM: Fitting mechanistic epidemic models to data: A

In ‘Revealing the extent of the first wave of the COVID-19 pandemic in Kenya based on serological and PCR-test data’ the authors use a range of statistical and mechanistic approaches to investigate the first wave of the pandemic in Kenya using both serological and PCR-test data. Overall, the authors have done an excellent job at integrating appropriate methods with available data sets to provide a useful investigation into transmission patterns in Kenya. Given the dearth of analyses from Sub-Saharan Africa countries, this manuscript is a welcome addition. Overall, I have few comments, the majority of which are minor and outlined below.

The authors have analyzed transmission patterns across all counties in Kenya, yet only show those for the two most populous (Nairobi and Mombasa) and a country-level result. While this is reasonable for the main text, I believe that adding in results by county to the supplementary information would help the interpretation of the country-level results. Particularly given likely differences in testing and reporting by county, a better understanding of the overall estimates of model predictions and Rt estimates by county would be incredibly valuable. For example, the authors provide the percentage infected by county in Figure 3, however these values are different to interpret in context, particularly without seeing the data and estimates by county.

In Figure 1 (C,D) the model prediction CIs are incredibly narrow, which seems surprising. Does this occur across the country? Or is this mainly due to the higher quality data in both Nairobi and Mombasa?

In Figure 2, it would be helpful (perhaps in the supplement or in this main figure) to provide context on when restrictions were lifted in addition to when they were put in place. Further, it is interesting that the IQR for the Rt estimates early in the pandemic seem exceptionally narrow. Additional elaborations on these points (is it likely due to overfitting? Some factors associated with the model fitting? Etc.) should be included. In addition, the Rt estimates for Mombasa in August/September seem substantially different than the rest of the country. Can the authors...
provide additional context? And do they see similar patterns across the coastal counties during this time?

The authors do an excellent job appropriately combining different data sets, which is well explained in the supplementary information. Some of these details would be incredibly helpful to move to the main text, in particular additional detail on how the authors treat the serological versus PCR data (and when there were both negative and positive PCR results) and how these two pieces of evidence are integrated.

Finally, in the supplement the authors use the phrase ‘Chinese epidemic’, but a small point that it may be more appropriate to say ‘epidemic in China’.

**Is the work clearly and accurately presented and does it cite the current literature?**
Yes

**Is the study design appropriate and is the work technically sound?**
Yes

**Are sufficient details of methods and analysis provided to allow replication by others?**
Yes

**If applicable, is the statistical analysis and its interpretation appropriate?**
Yes

**Are all the source data underlying the results available to ensure full reproducibility?**
Yes

**Are the conclusions drawn adequately supported by the results?**
Yes

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** I am an infectious disease epidemiology focused on transmission modeling.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

The ideas presented in the paper are plausible, resulting to a model, although a simple SEIR model, that is robust and adequately reproduces the observed trajectory of infections.

It was captivating to see the authors express the force of infection in terms of the case data time series (which is as a result of "successful" contact between susceptible and infected individuals). This is arguably the only way a compartmental model can reliably reproduce the waves of infections observed in data. Also the notion of, only a proportion of the population is at risk, is a quite realistic.

There are a few typos, as indicated below:
- On page 3, column 2, in line 10 write as...declining, first in...
- On page 3, column 1, in line 20 write as ...SARS-CoV-2.
- On page 3, column 1, in third paragraph at line 5 write as ...already...

**Is the work clearly and accurately presented and does it cite the current literature?**
