Abstract

COVID-19 vaccination of children has begun in various high-income countries with regulatory approval and general public support, but largely without careful ethical consideration. This trend is expected to extend to other COVID-19 vaccines and lower ages as clinical trials progress. This paper provides an ethical analysis of COVID-19 vaccination of healthy children. Specifically, we argue that it is currently unclear whether routine COVID-19 vaccination of healthy children is ethically justified in most contexts, given the minimal direct benefit that COVID-19 vaccination provides to children, the potential for rare risks to outweigh these benefits and undermine vaccine confidence, and substantial evidence that COVID-19 vaccination confers adequate protection to risk groups, such as older adults, without the need to vaccinate healthy children. We conclude that child COVID-19 vaccination in wealthy communities before adults in poor communities worldwide is ethically unacceptable and consider how policy deliberations might evolve in light of future developments.

Amendments from Version 1

We are grateful to the reviewers that have given us valuable feedback on the first version of our open letter. We have edited this piece accordingly. We have made the ethical framework of analysis more explicit, both in the introduction and in the last paragraph of the open letter. We also refer to the relevant public health ethics literature for several more specific arguments (e.g., in the “Protecting risk groups does not require vaccinating children” section). We also grapple with a common the individual risk/benefit calculus for COVID-19 vaccination: even if there is some risk to children, the benefit of decreased onward transmission is worth it—i.e., that children potentially assume risk for population-level benefits. We specify that our analysis is targeted for young, healthy children (e.g., those aged under 15 with no comorbidities), acknowledging that relevant considerations may change in older children or those with significant medical conditions. We also added in discussion regarding the threat of multisystem inflammatory syndrome (MIS-C) death resulting from COVID-19 infection, which is an important consideration in weighing the costs and benefits of child vaccination against COVID-19. We also contextualize our analysis in the context of other vaccine-preventable childhood diseases, specifically chickenpox. Additionally, we added in references regarding the suspension of Moderna vaccine administration to younger age groups in Nordic countries. We also grapple with the risk that COVID-19 vaccination could pose to children who have already recovered from COVID-19.

Any further responses from the reviewers can be found at the end of the article

Introduction

There has been relatively little ethical analysis of vaccinating children against COVID-19. While the approval of a COVID-19 vaccine for children is a testament to rapid scientific progress during the pandemic, applications of scientific achievements are not by default ethically sound. In this piece, we explore the ethics of vaccinating children against COVID-19 from a global public health ethics perspective, given the: minimal direct benefit for young healthy children, the potential for rare risks to outweigh such benefits or undermine vaccine confidence, and increasing evidence that COVID-19 vaccination of risk groups such as older adults adequately protects these groups without the need to vaccinate children. We expand our analysis to the global level, highlighting international inequities of COVID-19 vaccine availability and burden of disease. Finally, we discuss potential scenarios in which there could be a stronger ethical case in favor of vaccinating children against COVID-19. We conclude that it is currently difficult to ethically justify the routine vaccination of healthy children, especially given inequitable global vaccine availability.

Minimal benefit to healthy children

Our ethical analysis is focused on young healthy children (e.g., those aged under 15 with no comorbidities), acknowledging that relevant considerations may change in older children or those with significant medical conditions. Overall, the risks of severe illness are markedly lower in young children than in older adults, and children are also less susceptible than adults to becoming infected with the virus. The emergence of the Delta COVID-19 variant has led some commentators to argue that child COVID-19 vaccination is justified by relevant differences between this and previous variants. We challenge this claim, for there is currently “no clear evidence that children are more vulnerable to or more affected by Delta compared with earlier variants." The burden of COVID-19 in children is similar to or lower than that of typical seasonal influenza during the winter. Nevertheless, the rare cases of children hospitalized with COVID-19 may be severe, and children with certain comorbidities may be at higher risk. It may well be justifiable to trial and eventually use vaccines routinely in children with certain comorbidities, but it is much harder to justify the vaccination of healthy children on the basis of expected benefits to them, given the extremely mild average disease severity. Further, post-infection immunity is at least as effective as vaccination at protecting against (re-)infection in later life, which might otherwise have been more severe.

With this in mind, healthy children can suffer significant adverse effects from COVID-19, but these outcomes are rare. The disease rarely causes severe inflammatory states and death in healthy children, and such outcomes are more common among children with significant comorbidities. Every child death is a tragedy. Still, current data suggests these cases to be a small minority of COVID-19 cases among healthy children. It is sometimes claimed that even healthy children frequently experience significant post-acute symptoms ("long covid") after mild or asymptomatic infection. However, careful analyses of available data have shown this to be unsupported by current evidence. Though some COVID illness duration in children is prolonged, research suggests that the burden of symptoms does not increase with time. Likewise, post-COVID-19 fatigue is strongly correlated with the severity of the acute illness in adults. Since COVID-19 is generally mild or asymptomatic in healthy children, it is implausible that post-acute symptoms would frequently be severe. Thus, protecting healthy children against long covid does not in itself provide sufficient justification for routine COVID-19 vaccination of healthy children.

Ultimately, unlike many other vaccine-preventable diseases, healthy children are at low risk of COVID-19 morbidity, and mortality. As long as COVID-19 cases remain on average mild or asymptomatic in children, very large numbers of children would need to be vaccinated to prevent one pediatric COVID-19 hospital admission. In our view, routine or mandated COVID-19 vaccination of healthy children cannot be justified on the basis of direct individual benefits, and any small, expected benefit may be outweighed by risks and uncertainties.

Potential risks in children

Policymakers should be especially cautious about potential risks of COVID-19 vaccines in children. First, because avoiding harm to healthy children is arguably key to maintaining vaccine confidence. Second, because there are risks associated...
with, for example, current mRNA and viral vector vaccines\(^1\). Since the expected benefits of COVID-19 vaccination in children are low, even rare harms are highly salient to the ethical acceptability of routine healthy child vaccination with any COVID-19 vaccine. Initial safety data from the clinical trials that motivated the EUA authorization of the Pfizer-BioNTech vaccine for children included 2,260 participants aged 12 to 15, of which 1,131 received the vaccine, and the remainder (1,129) received a placebo\(^2\). Recent data suggest that myocarditis is an important rare harm associated with mRNA vaccination, affecting primarily adolescents and young adults, more commonly occurring after the second dose of vaccine, and with a rate in males approximately 10 times that in females\(^3\).

Although long-term harms related to vaccines are rare, there should ideally be prolonged follow-up of pediatric trial participants before routine COVID-19 childhood vaccination, especially given the minimal expected direct benefits vaccination would provide for children\(^4\). Traditionally, childhood vaccines are developed over decades, with clinical trial safety testing continuing for years, as was the case for the chickenpox vaccine\(^5\). Pfizer released the topline adolescent (12–15 years old) data\(^6\), which might at least rule out common adverse events occurring less than eight months post-vaccination. Still, more data are needed. Since relatively few children were involved in the Pfizer-BioNTech clinical trials, and follow-up has not yet been of long duration, regulators are arguably poorly placed to evaluate the risks of rare or delayed adverse outcomes\(^7\). Sweden, Norway, and Finland have suspended use of the Moderna COVID-19 vaccine in young people “as a precaution” following the increased detection of adverse side effects such as myocarditis and pericarditis\(^8\). Initial data on the long-term outcomes of mRNA-vaccine associated myocarditis, for example, are due to be published in late 2021\(^9\). Moreover, COVID-19 is not a pediatric public health emergency\(^10\). As a result, we agree with other authors who have suggested that standard criteria for EUA authorization of the Pfizer-BioNTech COVID-19 vaccine for use in children have not been met\(^11\).

Historically, vaccine-related harms to children and overly hasty pediatric vaccine rollouts have undermined public confidence in vaccines and cost lives. For example, by the time the risks of a licensed dengue vaccine to a minority of children were confirmed, the Philippines had already vaccinated 830,000 children, many of whom faced increased disease risks if they had never been infected with dengue before\(^12\). As a result, at least 130 children died\(^13\). Public trust in other vaccines collapsed, leading to local outbreaks of measles and increased risks of other vaccine-preventable diseases\(^14,15\).

Moreover, after the 2009 influenza pandemic, children were identified to be at a greater risk of narcolepsy as a rare vaccine-related harm (five-to-fourteen-fold increase in children as opposed to a two-to-seven-fold increase in adults)\(^16\). As a result, some public health authorities suspended the use of this vaccine in children amid public controversy\(^17\).

Defects in vaccine production can also pose unintended negative adverse effects in children. Historically, production defects with polio vaccines, for example, were associated with at least one high profile case of harmful outcomes in children, which undermined vaccine confidence at the time\(^18\). While the Pfizer-BioNTech vaccine is not a live-attenuated virus, defective production has already occurred for COVID-19 vaccines (e.g., ingredient conflation in 15 million doses of the Johnson & Johnson vaccine)\(^19\). Were such defects to go undetected, they might pose harm to vaccine recipients, which, for the reasons outlined above, would be especially concerning in pediatric populations\(^20\).

Public trust in vaccines, particularly child vaccines, takes years to build and days to break. Rare or long-term vaccine-induced risks in children, whether due to defective production or intrinsic to the vaccine but not detected in prior studies, have thus undermined public confidence in the associated vaccines and vaccines in general\(^21,22,23\). This remained true even when the harms were very rare and if there was an ex-ante net benefit in children. Since it is currently unclear whether mRNA vaccines for COVID-19 are associated with a net benefit in young healthy children, vaccine policy should proceed with caution\(^24\). This is especially true for healthy children who have post-infection immunity to COVID-19, in whom the benefits of vaccination are likely even smaller and the risks even more uncertain due to lack of data in this group, who (despite this) may receive vaccines as part of routine or mandated policies.

Rather than hastily expanding the use of COVID-19 vaccines in children, a more responsible approach would be to prioritize the systematic collection of pediatric safety and effectiveness data, ideally in placebo-controlled studies. Such studies remain ethical, including from the point of view of equipoise, since it is currently a matter of debate whether the benefits of mRNA vaccines outweigh the risks in healthy children. Such studies could be simultaneous with expansion of access for adolescents with comorbidities in whom the individual benefits more plausibly outweigh risks. If the risks or uncertainties related to mRNA vaccine use in children using standard schedules turn out to be unacceptably high, policymakers could also consider testing single mRNA dose regimens (given that risk of myocarditis appears to increase significantly with the second dose) and/or more widespread use of other types of vaccines (e.g., whole inactivated virus vaccines), which may have a more acceptable safety profile in children\(^25\).

**Protecting risk groups does not require vaccinating children**

Child vaccination is often partly justified by the need to prevent the spread of infections from healthy children to others, including (non-pediatric) risk groups\(^26,27\). Some may argue that the risk posed to healthy children by COVID-19 vaccination may be justified by the benefit of decreased onward transmission, at least if this benefit proves to be significant and sustainable over the long term with current vaccines. We reject this claim. Older adults and other COVID-19 risk groups can be protected without vaccinating children for at least two reasons. First, because children are responsible for a relatively small fraction of transmission outside of households. Second, because COVID-19 vaccines are highly effective against severe disease...
even where vaccinated individuals are exposed to infection, whether by children or adults.

Data suggest that children are less susceptible to developing SARS-CoV-2 infection and, even if infected, are less likely to infect others as compared to adults\(^4\). The majority of secondary infections directly attributable to children occur within households. If adult household members are vaccinated, the risks to the wider community may be reduced still further\(^4,4\). Though controversy persists regarding the effect of school closures on COVID-19 community transmission, recent data suggest that reopening schools does not result in large resurgent epidemics of severe disease in populations where a large proportion of adults are vaccinated\(^4,4\). In sum, children are not major vectors of COVID-19 transmission, insofar as their risks of becoming infected are lowered further by high rates of adult vaccination.

Perhaps the strongest case against child COVID-19 vaccination is the fact that COVID-19 vaccines are safe and effective in higher-risk groups, including older adults and the immunocompromised\(^4\). Ethical arguments in favor of vaccinating healthy, young people for the benefit of others in the context of other diseases generally emphasize that the generation of population (“herd”) immunity is one of the only ways to protect vulnerable risk groups\(^4\). Such risk groups may be unable to generate a sufficient immune response to other vaccines, such as those for influenza and pneumococcus\(^4\). In these cases, risk groups might depend on healthy children to get vaccinated in order to protect others. This is not the case for COVID-19. Risk groups experience highly effective protection against severe COVID-19 from currently available vaccines, even if they are exposed to significant community transmission\(^4\). As a result, the ethical claim that young, healthy children should get vaccinated especially for the benefit of risk groups—which might constitute a strong argument in favor of the vaccination of healthy children against other diseases—does not hold in the case of COVID-19 vaccines\(^4\).

Overall, the contribution to population-level immunity per child vaccinated is significantly lower than the contribution per adult vaccinated. Inadequate vaccination of adult populations should not be an excuse for the vaccination of children. Furthermore, it would be poorly cost-effective and ethically unjustified to use children as a means to protect vaccine-hesitant adults—especially if vaccinating children involves non-trivial risks.

Once a high proportion of adults are vaccinated, if residual transmission levels and disease burden are deemed unaccept-able, COVID-19 vaccination of children might, under certain conditions, produce additional reduction in these outcomes. Such conditions may include higher risk individuals who happen to be poorly protected by vaccines remaining at risk by exposure to otherwise-healthy children infected with COVID-19. Until adult vaccination uptake in communities is maximized, it is not clear that it would be ethically justifiable to promote COVID-19 vaccination of children to boost population immunity. Moreover, since current COVID-19 vaccines do not provide sterilizing immunity, and since post-vaccination infections are relatively common, no amount of community vaccination will produce elimination of transmission. Vaccinated adults will be infected sooner or later. While higher rates of child vaccination might delay infections in some adults to some degree, these infections cannot be prevented. The ubiquity of post-vaccination infections and re-infections therefore undermines the weight of any ethical argument to the effect that vaccinating children is required to prevent harm to others.

**Perpetuation of global vaccine inequities**

The COVID-19 pandemic has been characterized by domestic and international inequities\(^5\), including but not limited to inequities in the distribution of the burdens of disease, scarce healthcare resources, social and economic opportunities, and, most recently, vaccines\(^5\). As of April 2021, 700 million COVID-19 vaccine doses had been globally administered, with high income countries (HICs) securing 87% of doses, and low-income countries (LICs) securing only 0.2% of doses\(^5\). These inequities are further exacerbated by the administration of ‘booster’ vaccines in HICs, while LICs remain without first and second doses. Israel now administers ‘booster’ doses to all eligible individuals five months after their second dose\(^5\), while Germany, France, and the United States anticipate boosting all eligible individuals from September 2021\(^5\). Though many HICs have committed to donate COVID-19 vaccine doses to low- and middle-income countries (LMICs), these donations are only a small fraction of the 1.8 billion dose goal of COVAX and are not a sustainable solution to equitably vaccinating higher risk individuals worldwide\(^5\).

Vaccinating adults in LMICs alongside those in HICs is arguably the best way of ensuring global equity and ensuring positive child health and wellbeing outcomes\(^5\). Adults are often the key support for one or more children and other vulnerable populations, such as older adults\(^5\). When that support system is threatened, either through illness or death, children suffer socially and economically. As a result, children may have to stop attending school, or other social services, in order to work—or may be forced into child marriages, which have increased in frequency during the pandemic\(^4\). Accordingly, the social benefit of vaccinating adults, particularly in LMICs, far outweighs the benefit of vaccinating healthy children in HICs\(^5\). As a global community, we should focus on vaccinating adults in LMICs—beginning with healthcare workers and older adults and lowering the age as supply increases—rather than healthy children in HICs.

**COVID-19 vaccine policy and potential future developments**

Ethical evaluations of routine childhood vaccination against COVID-19 are, of course, subject to future developments. First, international travel has not returned to pre-pandemic levels (and many countries’ borders have been closed or entry restricted)\(^5\). An increase in travel might increase transmission—though not necessarily affecting disease burden to the same degree, provided that vaccines and post-infection immunity remain effective in the prevention of severe disease.
Second, the UK and Israel have a high level of population immunity due to past infection, whereas countries that largely eliminated COVID-19 (for example Australia, New Zealand, or Taiwan\textsuperscript{65}) might require even higher rates of adult vaccination to achieve similar levels of disease control. Third, vaccine-derived immunity may wane over time, especially where individuals are not re-exposed to infection soon after vaccination.

As a result, one might think that there would be contexts in which child COVID-19 vaccination would be more ethically acceptable on a routine basis than is currently the case. However, some factors leading to unacceptable disease burdens could be mitigated with other measures. For example, waning immunity could be controlled by repeat ‘booster’ COVID-19 vaccination of vulnerable adults\textsuperscript{66}. Moreover, since SARS-CoV-2 will likely become globally endemic\textsuperscript{67}, causing mild childhood illness akin to other seasonal human coronaviruses, post-infection immunity in children will also make a positive contribution to disease control. The case for vaccinating children might therefore become even weaker in the long term since post-infection immunity will be well-matched to circulating variants and robust across closely related variants as is known to be the case for other coronaviruses\textsuperscript{68,69}. Post-infection immunity in children might thus be expected to provide more sustainable public health benefits than a reliance on regular updates of vaccines.

Furthermore, there is increasing evidence that COVID-19 vaccines do not altogether prevent infection\textsuperscript{70}. This creates a concern that by vaccinating children, infection may only be delayed (through waning vaccine efficacy), thus instigating the potential need for ‘booster’ shots. While the risk-benefit profile of offering ‘boosters’ to groups at high risk may turn out to be favorable, this is unlikely to be the case for children, given the previously discussed low net benefits of COVID-19 vaccination and the potential for any harms to outweigh those benefits.

Despite some public health officials suggesting otherwise, and even going so far as to advocate for mandatory child COVID-19 vaccination\textsuperscript{80}, the Delta variant currently does not threaten the feasibility of high adult COVID-19 vaccination uptake to control disease burden. As a result, the ethical acceptability of routine COVID-19 vaccination of healthy children is currently weak – and the case for mandating even weaker. Nevertheless, should high adult vaccination uptake be insufficient to control disease burden – as opposed to mere transmission of the virus – a stronger case for routine child COVID-19 vaccination could emerge. Even then, however, there may still be ethical reasons to target adult populations before children\textsuperscript{89}. Additionally, the ethical acceptability of routine child COVID-19 vaccination under any circumstances is contingent on reliable long-term safety data from clinical trials involving children. Should severe side effects arise in healthy children, even if they are rare, the overall public health harms of vaccinating healthy children, including reductions in vaccine confidence, may outweigh any benefits.

Ultimately, parents and guardians of children should weigh the potential risks and benefits of vaccination in their own context. Currently, every vaccine used for a healthy child in a wealthy community would most likely be better used for an adult at high risk of severe illness from COVID-19 in a poor community. Perhaps in the future, should global vaccine supply be sufficient to meet demand, and should more data become available regarding the long-term safety of COVID-19 vaccines in children, ethical considerations might weigh in favor of COVID-19 vaccination of children, without making COVID-19 vaccines routine or mandatory for all children. At present, especially from a global public health ethics perspective, routine vaccination of healthy children against COVID-19 on balance, to be unjustified.

This is an excellent letter. It is very important and timely. The only things I recommend the authors consider would be:

1. Making clearer what the current argument for vaccinating all children is - such as acknowledging there have indeed been deaths among healthy children and that MIS-C also poses a threat to healthy children. I think addressing these specific issues will make the letter stronger.

2. It would be good to put the COVID-19 vaccine in the context of other routine childhood vaccinations - why they are recommended for children and how the amount of safety data we have on those differs from what we have the COVID-19 mRNA vaccines.

3. Consider mentioning the suspension of Moderna in younger age groups in Nordic countries.

4. Please also consider mentioning the much smaller potential benefit to children who are already immune and how the risk of the vaccination would most certainly outweigh the benefit in most of these children.

Thank you. I commend all of the authors on the excellent work.

Is the rationale for the Open Letter provided in sufficient detail?
Yes

Does the article adequately reference differing views and opinions?
Partly

Are all factual statements correct, and are statements and arguments made adequately
supported by citations?
Yes

Is the Open Letter written in accessible language?
Yes

Where applicable, are recommendations and next steps explained clearly for others to follow?
Yes

**Rachel Gur-Arie,** Johns Hopkins University, Deering Hall, 1809 Ashland Avenue, Baltimore, USA

This is an excellent letter. It is very important and timely. The only things I recommend the authors consider would be:

Making clearer what the current argument for vaccinating all children is - such as acknowledging there have indeed been deaths among healthy children and that MIS-C also poses a threat to healthy children. I think addressing these specific issues will make the letter stronger.

- Thank you for this suggestion. We have incorporated this point into the ‘minimal benefit to healthy children’ section: “With this in mind, healthy children can suffer significant adverse effects from COVID-19. A multisystem inflammatory syndrome (MIS-C) has been associated with COVID-19 among healthy children, and healthy children have died from COVID-19. Every child death is a tragedy. Still, current data suggests these cases to be a small minority of COVID-19 cases among healthy children.” We have also added two references.

It would be good to put the COVID-19 vaccine in the context of other routine childhood vaccinations - why they are recommended for children and how the amount of safety data we have on those differs from what we have the COVID-19 mRNA vaccines.

- Excellent point, thank you. We have added in an example of the chickenpox vaccine in the “potential risks to children” section.

Consider mentioning the suspension of Moderna in younger age groups in Nordic countries.

- Thank you for this suggestion! We have added this in to the “potential risks in children section and added the reference: Paterlini, M. (2021). Covid-19: Sweden, Norway, and Finland suspend use of Moderna vaccine in young people “as a precaution”. BMJ.
Please also consider mentioning the much smaller potential benefit to children who are already immune and how the risk of the vaccination would most certainly outweigh the benefit in most of these children.

- Thank you for suggesting incorporating this important nuance. We have included it in the “potential risks to children” section: “The small potential benefit to healthy children who have post-infection immunity to COVID-19 would most likely be outweighed by the potential risks of COVID-19 vaccination.”

Thank you. I commend all of the authors on the excellent work.

- Thank you for reviewing our manuscript!

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 22 Nov 2021
Rachel Gur-Arie, Johns Hopkins University, Deering Hall, 1809 Ashland Avenue, Baltimore, USA

This article is focused on providing a synthesis of the ethics of COVID-19 vaccination for children.

Overall, I think an evidence-based synthesis that it remains unclear even within communities to vaccinate all young children with the currently available vaccines and also that it is particularly challenging in the context of global vaccine inequities. The strengths are clear in that it takes a neutral tone and is data-driven. However, I believe it could be strengthened in a few ways.

- Thank you!

Since it is not a systematic review, I believe the way to maximize the potential impact of the work is to present it in the context of a broadly accepted ethical framework. It may be a single framework that evaluates the individual risk:benefit ratio of vaccination and then another one that evaluates it globally—or maybe the same framework if feasible. Either way, I think presenting it this way will go a long way in terms of the transition from this being a commentary to more of an ethical analysis.

- We agree with you that the best way to present our open letter is in the context of a broadly accepted ethical framework. The framework adopted in this open letter is the
ethics framework of global public health ethics. As bioethicists, we recognize that the framework in the open letter's first version is very implicit, and we have edited accordingly to make our framework of analysis more explicit, both in the introduction and in the last paragraph of the open letter. We also refer to the relevant public health ethics literature for a number of more specific arguments (e.g., in the “Protecting risk groups does not require vaccinating children” section).

At the individual level, I also think including the argument that is often used about even if there is some risk to children, the benefit of decreased onward transmission is worth it—i.e., that children potentially assume risk for population-level benefits. It would be helpful that the ethical analysis includes an assessment of this within broadly accepted ethical frameworks.

- Thank you for this suggestion, and we believe that our arguments in the “Protecting risk groups does not require vaccinating children” section support this claim. However, we have added your exact language to the beginning of the section to make this line of reasoning clearer.

Separately, I think the paper would do better by specifying the age of children being included in the analysis. Is this <18, 12-15, <12, etc as the analysis may vary based on this.

- Thank you for this clarification. We are conducting this analysis specifically for: “young healthy children (e.g., those aged under 15 with no co-morbidities), acknowledging that relevant considerations may change in older children or those with significant medical conditions” and have now specified that in the open letter.

**Competing Interests:** N/A
